When information is communicated to a
user, the information is often subject to
noise. The noise may be related to what is
communicated, in which case it may be
noise in the signal or noise in the
medium. Alternately, the noise may be
unrelated to what is communicated, in
which case it may be noise in the channel.
One example of the latter is a channel in
which one or more of the components of
the channel are prone to in-band or out-of-
band interference. When the noise is not
noise in the signal, it may be desired to

mitigate the noise such that the signal can be communicated to the user. Examples of such noise include out-of-band interference from a co-located (or collocated) system, or interference from other frequency bands in the spectrum. Other examples of such noise include multi-path interference and in-band interference from noise or from an undesired system (such as a co-located or collocated system or other frequency band in the spectrum). Conventional mitigation schemes typically involve the generation of artificial noise. Artificial noise can be applied to the signal in a channel (e.g., in-band or out-of-band), or, more generally, can be applied to the

channel (e.g., a co-located or collocated system or a frequency band in the spectrum). However, generating artificial noise, which has the same characteristics as the interference, is a significant challenge, particularly when the noise is random. }
